Road to Productivity: The Effect of Roads on Manufacturing TFP in India

Subham Kailthya[*]   Uma Kambhampati[†]

This version: July 25, 2018

Abstract

In this article, we examine the effect of roads on Total Factor Productivity (TFP) in Indian manufacturing. We exploit exogenous variation in the timing and duration of partisan alignment of states with the centre that affect implementation of road projects to identify the impact of roads on manufacturing TFP during 1998-2012. After controlling for endogeneity of road placement, we find that an increase in road density leads to a 0.10-0.34 log point increase in TFP at the industry level or, about a 12 percentage point increase in TFP for each percent increase in road density. We find heterogeneous impact of roads on TFP: smaller firms, incumbents and industries in urban states see higher TFP gains than their respective counterparts. Furthermore, long-differenced results suggest that besides scale-effects, improving road density affects the growth rate of TFP. Placebo tests on our instrument and several robustness checks reinforce our findings.

1 Introduction

Transportation plays a vital role in stimulating economic growth. But, in many emerging economies including India and China, inadequate transport infrastructure poses a formidable barrier to manufacturing growth (Jedwab and Moradi 2016, Ghani et al. 2016a). For instance, the World Bank Enterprise Survey (WBES) reports that one in every ten manufacturing firms in India in 2014 identifies (lack of) transportation as a major obstacle (WB 2014).[1] To ease the movement of goods, services and people within the country and stimulate economic growth, many developing countries have embarked on ambitious multi-billion dollar infrastructure projects funded by an increasing share of their public budgets.[2] Yet, our understanding of how transportation affects economic activity, particularly how it affects manufacturing productivity in developing countries, is far from complete. To date, a majority of studies that consider the impact of transportation on economic activity in developing countries have adopted two broad approaches. The first approach focuses on evaluating the impact of showcase transport projects such as the Golden Quadrilateral (GQ) project in India (see Ghani et al. 2016a,b, Datta 2012, etc.) or the National Trunk Highway System (NTHS) in China (see Faber 2014) that offer project-specific insights. The second approach considers the effect of a synthetic index of infrastructure that comprises a range of infrastructure variables (see Mitra et al. 2002, 2012, etc.). Because the contribution of individual components in the latter approach is not separable, it is not well suited to learning how transportation *per se* affects manufacturing productivity.[3] In contrast to these approaches, in this article we analyse how India's entire road infrastructure affects Total Factor Productivity (TFP) in the manufacturing sector. This allows us to draw generalized insights about the contribution of roads in increasing manufacturing productivity within a developing country context. For the purpose of this study, we use panel data from the Annual Survey of Industries (ASI), a nationally representative survey of organized manufacturing in India, for the period

---

[1] Inadequate transport infrastructure is both a regional and a global constraint: about 21% of manufacturing firms surveyed in South Asia and around 19% of firms surveyed across all countries in the WBES during the years 2010-2017 indicate lack of transport infrastructure to be a significant obstacle. See http://www.enterprisesurveys.org/. Lack of adequate infrastructure has also disadvantaged infrastructure-dependent plants in benefiting the most from a liberal policy environment such as the de-licensing of product space in Indian manufacturing (Gupta et al. 2008).

[2] For instance, India's 2017-18 budget announced a record spending of Rs.3.96 trillion ($59 billion) to build and modernize its transport infrastructure network to provide 'renewed impetus' to manufacturing. This includes an allocation of Rs.649 billion for road building, a 12% rise in comparison to the previous budget (Bloomberg 2017). This stands in sharp contrast to the increase in expenditure allocation towards healthcare and education, which grew by 2.76% and 3.84%, respectively.

[3] While focusing on showcase transportation projects offer detailed project-specific insight, they may not be generalizable. If we consider that showcase projects are often carefully selected to maximize economic returns at low social/ political cost (e.g. projects that have low land acquisition costs or are located in politically favoured states), the findings from these studies may be closer to the upper bound instead of resembling the average effect. On the other hand, studies that use an aggregate index of infrastructure that includes roads, railways, electricity and a host of other infrastructure variables cannot easily disentangle the impact of its individual components and hence offer limited policy insight. Hulten et al. (2006) is an exception that studies the impact of national and state highways on Indian manufacturing productivity but does not control for endogeneity.

1998-2012. We concentrate on roads because it is the predominant mode of transportation in India accounting for 65% of freight movement and 80% of all passenger traffic (NHAI cited in Ghani et al. 2016a).

Transport infrastructure can affect economic activity in several ways: First, a robust and reliable transport network integrates distant markets through lower freight rates and improved travel times. The arterial network of roads and railways have played a fundamental role in increasing trade through improved market access. This relationship has been extensively documented (see, for example, Fernald 1999, Chandra and Thompson 2000, Michaels 2008, Duranton et al. 2014, Holl 2016, Redding and Turner 2015, among others).

Secondly, the reliability of transport network affects a firm's logistics throughout the different stages of production: it affects procurement and storage of raw materials and intermediate inputs as well as delivery of finished goods. A reliable transport network lowers uncertainty at both the procurement and supply stages thereby reducing the need to hold on to large inventories (Shirley and Winston 2004, Li and Li 2013, Datta 2012). The cost-saving aspect is particularly relevant for developing countries where inventory levels are generally two to five times higher in comparison to that of United States, the developed country benchmark (Guasch and Joseph 2001). Gulyani (2001), for instance, examines the Indian automotive sector and finds that the 'total logistics cost' of inadequate transport infrastructure is very high. In a similar vein, Datta (2012) estimates that being on the GQ highway reduces inventory holdings by at least six days' worth of production. Hence, a larger and spatially diversified market combined with the ability to operate at lower inventories due to a reduction in transport costs encourage producers to adopt leaner production structures that get reflected in manufacturing productivity.

The constraints posed by inadequate transportation infrastructure are analysed by Storeygard (2016) who use night-time luminosity as a proxy for the economic size of cities which typically concentrate manufacturing activity in Africa. Using global oil prices to provide exogenous variation in transport costs, they find that the economic activity of African cities that are further away from roads suffers more than cities that are nearer during high oil price years. In India, Ghani et al. (2016a) examine the impact of the Golden Quadrilateral (GQ) project on economic activity and find evidence of an increase in output and allocative efficiency in organized manufacturing in places located nearer to highways. In a similar study, they find that the GQ highway affects rural and urban areas differently: while the entry rates of firms are similar across both rural and urban areas, rural areas experience a larger increase in employment and output (Ghani et al. 2016b). Thus, the findings from past studies suggest that improving transport infrastructure in general, and roads in particular, is likely to increase manufacturing productivity although its impact might be heterogeneous both within and between industries.

An important challenge in estimating the impact of roads on economic activity is that their placement is not random (Banerjee et al. 2012, Shatz et al. 2011, etc.). For example, roads might be more prevalent in states that trade more i.e. when roads are built to support trade, or if they trade less, i.e. where roads are built to encourage trade (Duranton et al. 2014). Hence, state policies geared to attract specific industries might affect how much it invests on roads. Moreover, states with higher GDP are also likely to have larger resources to build roads. We overcome this inference problem by exploiting exogenous variation in the implementation of road projects due to political alignment of states with the central government. The premise is that, in a federal democracy, federal transfers favour states that are politically aligned with the centre over states that are not so aligned (see, for example, Sengupta (2011) for a theoretical framework and Arulampalam et al. (2009) for empirical evidence of partisan alignment boosting federal transfers in India). Politically motivated favouritism then increases the ability of aligned states to invest in visible transport infrastructure such as roads to improve their chances of victory in the next election. This exogenous variation in a state's road infrastructure, after controlling for railways and other state-specific fundamentals, allows us to maintain the exclusion restriction in identifying the effect of roads on TFP. Our study therefore provides a political-economic explanation for differences in manufacturing productivity across states that arise out of differences in access to transport infrastructure.

Another concern is that omitted variables such as differences in state-specific characteristics or access to alternative modes of transportation might confound the relationship between roads and manufacturing productivity. For example, firms might face different macroeconomic conditions that vary with its location such as the available labour pool, the skill set of workers, access to railways etc. all of which might affect productivity. To address this second concern, we control for year-interacted state-specific characteristics – population, literacy, total main and marginal workers, total workers in agriculture and industry – and a state's railway density to absorb the effect of potential confounders and allow for different time trends according to these characteristics. We also include state-industry fixed effects to control for state-specific policies toward different industries that might systematically affect industrial productivity within states. In addition, general economic conditions during a year such as the level of inflation in the country or the exchange rate situation might affect production orders or even the state's capacity to build roads. Hence, we include year fixed effects to control for such year-specific shocks. Once we include the full set of controls, we are reasonably confident in pinning down the impact of roads on productivity.

To preview our results, we find that an additional kilometre of road per square kilometre land area leads, on average, to a 0.10-0.34 log point rise in manufacturing TFP at the industry level. The impact of roads on TFP however differs by specific firm attributes such as incumbency status, its size and location: small firms and incumbents within the industry see higher gains in TFP, while firms in urban areas benefit more from roads.

To get a longer-term picture, we also analyse the impact that changes in road density has had on changes in industry level productivity between 1998 and 2012. We find that the results from these long-differenced regressions (noting that the dependent variable is in logs) are qualitatively similar to those from state-industry panel regressions with both showing a strong positive relationship between an increase in road density and a rise in manufacturing TFP. Thus, it illustrates that in addition to scale-effects, roads affect the growth rate of productivity. To get a more intuitive understanding of our results we conduct elasticity estimates and find that a one percentage point increase in road density leads to about a 12 percent increase in productivity, on average. We conduct placebo tests where we randomly assign alignment status – the placebo – as our instrument and a battery of robustness checks to ensure the reliability of our findings.

We organize the article as follows: In section 2, we discuss our data. In section 3, we focus on our estimation strategy where we specify a simple theoretical model that outlines the relationship between roads and TFP, discuss how we calculate TFP and present our identification strategy. In section 4, we report regression results on the effect of roads on industry-level TFP that accounts for endogeneity. We present results from robustness checks in section 5. Section 6 concludes.

2   Data

We combine detailed data on organised manufacturing in India with state-level data on transportation infrastructure and socio-demographic characteristics to create a state-industry panel running from 1998 until 2012. We discuss this below.

2.1   Manufacturing Data

We use establishment-level panel data on manufacturing activity during 1998-2012 to estimate TFP. We obtained this data from the Annual Survey of Industries (ASI), a pan-India survey of organized manufacturing establishments administered by the Central Statistical Organization (CSO), Government of India. While ASI covers the entire country, we exclude those Union Territories that do not hold legislative assembly elections from our sample. We will discuss this further in section 3.3. The ASI provides exhaustive data on the book values of a firm's assets and liabilities, employment and labour, receipts and expenses along with several other economic variables for a financial year (e.g. the 1998 survey reports data for 1998-99), but we will only refer to the initial year for simplicity.

The ASI covers organized manufacturing establishments registered under the Factories Act, 1948 that employ more than 10 workers if they use electricity in their manufacturing process or 20 workers if they do not. It follows a Circular Systematic sampling design that divides the sampling frame into two sectors: a census sector and a sampling sector. The

census sector consists of establishments in the states of Manipur, Meghalaya, Nagaland, Tripura and Union Territory of Andaman and Nicobar Islands where all establishments are surveyed or, in case of other states, establishments with more than 100 workers or those establishments filing joint returns i.e. returns for multiple units within a state. The sampling sector, on the other hand, consists of establishments not included in the census sector. The sampling design considers the state, sector and 4-digit NIC codes in stratifying the sample. Because of the survey design, we use the sampling multipliers provided by ASI throughout the article and cluster the standard errors of the regression coefficients at the state-industry level (see, Abadie et al. (2017) on clustering as a design problem). Thus, our results are representative of the entire population of manufacturing firms in the organized sector in India.

With the data at hand we construct an unbalanced panel of establishment-level economic activity starting from 1998, when ASI first released firm-level panel data, until 2012. While our data contains firm identifiers that allow us to observe individual firms over time, ASI, in compliance with the Collection of Statistics Act, 2008, no longer disseminates district identifiers after 2007. Hence, in this article, we conduct our analysis at the state-industry level. This helps us to factor in state-level endowments such as raw materials, labour pool, etc. which affect the location decisions of firms and hence the distribution of industries within a state. Another reason was that we wanted to cover a longer time span (i.e. to have larger Ts) to increase the precision of our estimates since even if we reverse engineered district identifiers, as in Martin et al. (2017), we could go only up to 2007 (after which ASI discontinued releasing district codes) whereas, with our approach using annual state-industry panel, we are able to extend our analysis further up to the year 2012 besides making it forward compatible as new data is released in future.[4]

2.2 Transport Infrastructure

As indicated earlier, our main covariate of interest is road infrastructure. We focus on roads since it is responsible for about 65% of freight and 80% of all passenger traffic in India (NHAI cited in Ghani et al. (2016a)). But using the total length of roads in a state might be problematic because states vary widely in their geographical size. To overcome this, we focus on road density, the total length of roads in a state divided by a state's land area, to obtain a normalised metric of access to roads in each state. Moreover, focusing on a physical measure of road transportation rather than the money value of investment in roads is advantageous: it ensures that our measure is free from distortions that might otherwise arise from price volatility; it is also less vulnerable to misreporting which is not an innocuous problem in weak institutional settings where transparency

---

[4]While we are aware of the matching method used in Martin et al. (2017) to recover the districts where a firm is located by matching economic variables from cross-section data that include district identifiers until 2007 and establishment panel which do not include district identifiers, we decided to go ahead with a state-industry panel for our analysis for reasons just mentioned.

and accountability is typically low. We obtained data on the total length of roads by state and year from the Ministry of Road Transport and Highways from 1998 until 2012. Summary statistics of our sample indicate that the average road density across states was 4.86 km/sq.km in 2012. Delhi had the highest road density of 21.6 km/sq.km whereas, Jammu and Kashmir had the lowest road density of 0.20 km/sq.km.

Railways present the main alternative to road transportation in India (see Donaldson (2018) on the impact of railways on trade in colonial India). Hence, to clearly identify the effect of roads on manufacturing productivity we need to include a state's railway density as a control variable in our model. To operationalise this, we gathered data on the length of railways (in route km) for every state during the study period from the Ministry of Railways and divided it by a state's land area, as in the case of roads.

2.3   Socio-Demographic Characteristics

We also include several key socio-demographic variables as controls in our model to reduce bias from omitted variables. These include population, literacy rate, main and marginal workers as well as data on total agricultural and industrial workers. Data for these variables are obtained from the 2001 census.

3   Empirical Strategy

3.1   Model Specification

To estimate the effect of roads on manufacturing productivity, we first estimate firm-level productivity as a function of local determinants (see Holl 2016, Martin et al. 2011) using a Cobb-Douglas production function:

$$Y_{it} = A_{it} K_{it}^{\beta_1} L_{it}^{\beta_2} \tag{1}$$

where Y_{it} is either the value added or gross output of firm i at time t. L_{it} denotes labour employed in production and, K_{it} is the capital stock of firm i at time t. We note that firm i belongs to industry j and is located in state s but we suppress the subscripts for simplicity. We then compute $A_{jst} = 1/n \sum_i A_{ijst}$ as the average TFP of industry j in state s at time t by taking the average across firms indexed $i = 1 \ldots n$ in industry j within state s at time t. A_{jst} depends on a vector of state specific characteristics, Z_{st}, and access to roads, $ROAD_{st}$. We adopt this approach because ASI data only allows us to identify the state where a firm is located, as already mentioned. Since our goal is to examine the effect of the total road network on industry-level TFP, analysis at the state-industry level

seems to be the most appropriate. We model productivity as:

$$A_{jst} = exp[\gamma(ROAD_{st} + Z_{st})] \tag{2}$$

We take log on both sides of eq.(1) to get:

$$y_{it} = \beta_1 k_{it} + \beta_2 l_{it} + \alpha_{it} \tag{3}$$

and for industry-level log TFP values from eq.(2) to get,

$$\alpha_{jst} = \gamma ROAD_{st} + \eta_{jt} \tag{4}$$

where lower case letters now denote the log of the respective variables. The term η_{it} might further include industry fixed effects, state-industry fixed effects or year effects that affect industry-level productivity along with a random noise term.

We therefore use a two-step estimation approach where we estimate firm-level TFP based on eq.(3) in the first step and obtain average industry-level TFP for different states across the years. In the second step, we use this productivity measure as the dependent variable to estimate the effect of roads in eq.(4).

3.2 TFP Measurement

In this study, we estimate TFP using both the value-added and gross-output definitions of production. We focus on multifactor productivity because differences in TFP reflect shifts in the production isoquants with higher-TFP producers on a higher isoquant than lower-TFP producers (Syverson 2011). We estimate TFP as the residual of a Cobb-Douglas production function as:

$$\alpha_{it} = y_{it} - \hat{\beta}_1 k_{it} + \hat{\beta}_2 l_{it} \tag{5}$$

where $\hat{\beta}_1$ and $\hat{\beta}_2$ are the input coefficients of capital and labour respectively, estimated at the 3-digit NIC industry classification using the Ackerberg et al. (2015) method (henceforth, ACF). We use the ACF method because: first, it accounts for the endogeneity of input choice in estimating productivity. The endogeneity arises because firms can observe their productivity before choosing inputs which means that inputs are likely to be correlated with productivity. Secondly, the ACF method overcomes the functional dependence problem that affects identification of the labour coefficient present in Olley and Pakes (1996) (OP) and Levinsohn and Petrin (2003) (LP) methods. Thus, while OP and LP invert investment (OP) and intermediate input (LP) demand functions that are unconditional on labour input, ACF inverts investment or intermediate input that are conditional on labour input to overcome functional dependence and correctly identify the labour coefficient in the first stage (see Ackerberg et al. (2015) for a detailed discussion
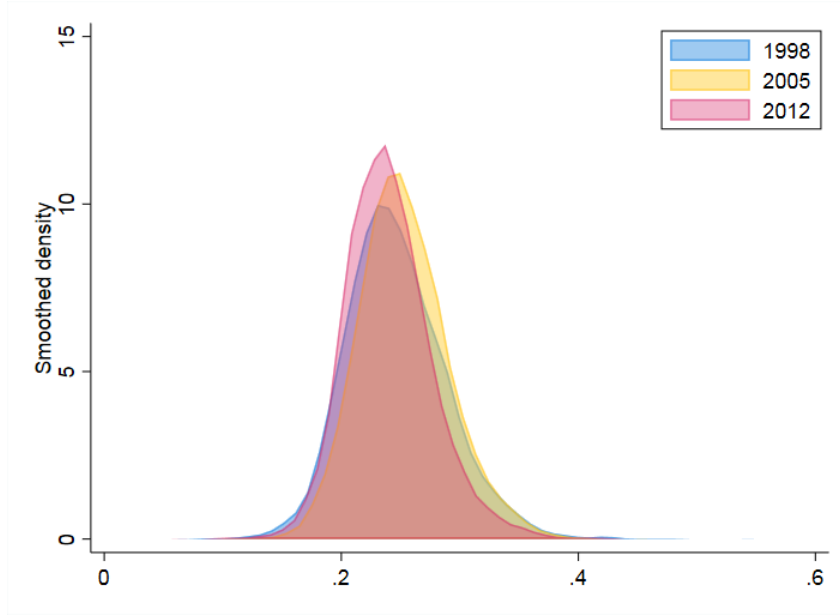

Figure 1: TFP in 1998, 2005 and 2012.
Figure plots the density of log value-added TFP in 1998, 2005 and 2012 where we normalise TFP values by dividing it by employment-weighted average productivity for an industry-year.

on the methodology and Matthias et al. (2016) for a recent application of this method). We note that our results using the ACF method are consistent with both the LP and the Wooldridge (2009) methods of estimating TFP.

To estimate TFP, we first deflate sales, labour, raw material, energy, and capital to arrive at their respective real values. Since the book value of capital is measured at historic costs, we use the perpetual inventory method (PIM) that accounts for differences in the vintage of capital stock. We then estimate firm-level TFP by 3-digit NIC industry classification (see Appendix A for the variables used in estimating TFP).

As a first step, we estimate firm-level TFP using 264 thousand observations covering 54 thousand establishments at 3-digit NIC level. Next, we normalise log TFP by dividing it by the employment-weighted average productivity (in logs) for an industry-year.[5] In Figure 1, we plot the log normalised TFP values for three different years 1998, 2005 and 2012. We observe that productivity increased consistently between the years and showed signs of increasing concentration of high-TFP firms in the industry.

We then calculate industry-level averages of log normalised value added TFP (TFP(VA)) and present summary statistics for this variable in Table 1. Table 13 in Appendix B provides summary statistics for log normalised gross-output TFP values (TFP(GO)). We observe that the log normalised industry-level TFP(VA) value is about 0.16 at the median for the entire sample. TFP is higher for small firms (0.20) in the industry than large (0.13) ones. The 90:10 percentile TFP ratio – a measure of dispersion of productivity

---

[5]This approach is followed in Ghani et al. (2016a). We adopt this approach for comparability and note that our results hold even without normalising the TFP values.

across industries – is about 3.7 illustrating that log productivity of industries at the 90th percentile is four times that of industries at the 10th percentile.

Table 1: TFP in Indian Manufacturing (Value Added), 1998-2012

Groups	Obs.	Mean	p10	p25	p50	p75	p90
All	6714	0.162	0.070	0.097	0.153	0.212	0.262
By Age:							
Young	5071	0.169	0.068	0.087	0.147	0.220	0.299
Incumbent	6595	0.163	0.069	0.095	0.155	0.216	0.267
By Size:							
Small	6333	0.202	0.069	0.101	0.192	0.277	0.345
Large	6173	0.128	0.069	0.085	0.116	0.155	0.201
By Location:							
Rural	3203	0.138	0.065	0.080	0.117	0.177	0.239
Urban	3511	0.186	0.086	0.129	0.187	0.230	0.274
$\text{TFP}_{2012}/ \text{TFP}_{1998}$	298	1.334	0.759	0.953	1.204	1.589	2.057

Notes: Table shows the dispersion of log value-added Total Factor Productivity (TFP) in Indian manufacturing during 1998-2012 estimated using the ACF method (Ackerberg et al. 2015). The firm-level log TFP values are normalised by dividing it by employment-weighted average productivity (in logs) for an industry-year. Row 'All' in the table corresponds to all observations in our sample. 'Young' includes industry-level estimates of only firms aged $\leq$ 4 years, whereas 'Incumbents' include those that are aged >4 years. 'Small' includes firms in the industry with fixed-assets lower than the median fixed assets in the industry, while 'Large' includes those with fixed assets greater than the industry median value. 'Rural' shows TFP for industries located in rural states where a rural state is defined to have urbanisation rate lower than the median value across all states in our sample. 'Urban' shows TFP for industries located in states where the urbanisation rate exceeds the median value. $\text{TFP}_{2012}/ \text{TFP}_{1998}$ is the ratio of log TFP values in 2012 and 1998.

3.3   Identification

Our identification strategy relies on three key aspects of India's political economy landscape: (a) fiscal dependence of states on federal funding for road building projects; (b) politically motivated tactical spending on 'visible' infrastructure projects by a state's ruling party; and, (c) the potential for manipulation of the size and timing of federal transfers to favour politically aligned states. The centre-state revenue dependence together with the potential for electoral gains from investing in visible infrastructure projects create strong incentives for the central government to favour federal transfers to politically aligned states. Owing to these institutional features, we use the political alignment of states with the centre as an instrument for road density.

In India, roads are predominantly publicly provided. While the central government funds the majority of road building works, the respective state governments are mainly responsible for its implementation. The size and timing of federal transfers allows aligned states to strategically increase their expenditure on public goods such as roads with the intention of strengthening the electoral position of incumbent parties. This is especially important when seats are tightly contested (Arulampalam et al. 2009, Johansson 2003,

Baskaran et al. 2015, Bracco et al. 2015).[6] In decentralized democracies, partisan alignment of lower-level jurisdictions with the centre leads to 'tactical', rather than 'programmatic' federal transfers that systematically affects the provision of local public goods (Solé-Ollé 2013, Solé-Ollé and Sorribas-Navarro 2008, Sengupta 2011, Khemani 2003).[7]

The hierarchical dependence relationship is likely to affect implementation of a range of development projects. But, perhaps 'visible' infrastructure projects are especially vulnerable to tactical/ targeted spending since the ruling party can credibly claim credit for the roads it builds as they are readily observable by the electorate (Mani and Mukand 2007). Wilkinson (2006), for example, documents that when Indian states hold competitive elections politicians announce several infrastructural projects with the aim of building political support and to raise money for campaign finance. These promised projects often remain incomplete after elections due to the high turnover of seats in state elections. Another related political-economic mechanism affecting infrastructure spending is the dynamic commitment problem within a coalition. Since infrastructure projects take time to complete, a different political party in power might shift the goal away from completing an on-going project onto their preferred projects that affect the probability of completion (Williams 2017). Hence, political economic factors are not incidental elements but often the key to when and where road projects are implemented.

We exploit the exogenous variation in partisan alignment between the state's ruling party and the centre over multiple election cycles as an instrument for road density. To operationalize this, we define a ruling party as the political party winning the maximum number of seats in a state for each legislative assembly election held between 1998 and 2012. We then construct a binary variable, *Aligned*, that takes a value of one if the state's ruling party is aligned with the centre (or the central coalition) and a value of zero if it is not aligned. To do this, we obtain data on state assembly election results during the period of our study from the Election Commission of India. In the context of coalition governments at the centre, we carefully map the various state parties with the coalition to account for any re-configurations (including parties dropping out during the life of the coalition government[8]).During our study period, the National Democratic Alliance

---

[6]Moreover, in parliamentary systems with single member districts, the chances of winning for the party is closely aligned with the performance of co-partisans which increases public provision that wins votes while reducing the incentive for corruption. As Bohlken (2016) points out, the role of partisan alignment is important because it is able to reconcile incentives for private rents that ministers keep to themselves (as argued in Lehne et al. (2018)) and providing public goods and controlling wider corruption in infrastructure projects.

[7]In India, the Finance Commission is responsible for determining the extent of equalization transfers from the centre to the states to neutralize vertical imbalance through a formulaic approach. But as Khemani (2007) notes 'formula-based transfers . . . have limited success in curbing political influence . . . the formula itself is determined by a political process or is not binding and leaves room for political discretion . . .'.

[8]For instance, the All India Anna Dravida Munnetra Kazhagam (AIADMK), a leading regional party in Tamil Nadu was part of the NDA alliance in parliamentary elections in 1998 but withdrew its support a year later leading to the BJP government's collapse and an early re-election in 1999 where AIADMK realigned with the Congress Party. We update the ruling coalition to account for any changes at the centre.
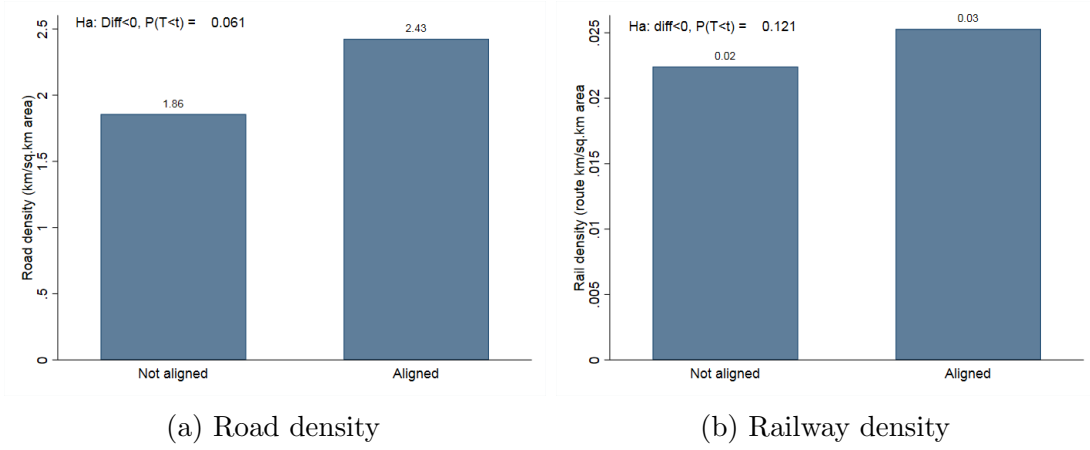

(a) Road density   (b) Railway density

Figure 2: Political Alignment and Transport Density: Road vs. Railway.
Panel (a) plots the average road density (in km per sq.km area) across Indian states for the duration for which states were Aligned and Non-Aligned respectively, during 1998-2012 whereas, panel (b) plots the average railway density (in route km per sq.km area) in a similar way. We observe that road density is higher when a state's ruling party is aligned with the centre in comparison to when it is not aligned. The difference is statistically significant with a p-value of 0.06 based on a one-sided t-test. For railway density, the difference is not statistically significant.

(NDA) headed by the Bharatiya Janata Party (BJP) was in power from 1998 until 2003, while the Congress Party-led United Progressive Alliance (UPA) was in power from 2004 to 2014. Finally, we drop Union Territories from our analysis because they do not hold legislative elections.

To what extent does political alignment affect road density? We engage with this question in Figure 2 panel (a), where we compare the average road density per sq. km land area of a state – our measure of access to roads – between aligned and non-aligned states. It shows that during 1998-2012, the average road density in aligned states was 2.43 km/sqkm area whereas, for non-aligned states the average road density was lower at 1.86 km/sqkm area. This difference is statistically significant with a p-value of 0.06 based on a one-sided t-test.

We then compare the density of roads with the density of railways between Aligned and Non-Aligned states. Ex-ante we would expect a state's road density to differ along partisan alignment status but less so for railways. This is because the extension of railways unlike roads, depends heavily on the historical networks that have been already laid out. Roads therefore are relatively easier targets to manipulate than railways. Figure 2 panel (b) plots the relationship between railway density and political alignment. We find that, as expected, while the difference between aligned and non-aligned states is statistically significant for road density, it is not so for railways. The finding that political alignment affects road density but not railway density increases our confidence in the choice of our instrument.

We now proceed to discuss our regression results.

4 Results

In this section, we present regression results on the impact of roads on manufacturing productivity. We structure our discussion by first presenting results relating to the average industry-level effect of roads on TFP. We then examine the heterogeneity in the impact of roads on the various segments within the industry – small vs. large firms in the industry, young vs incumbents and rural-based vs. urban-based industries – followed by a discussion on the elasticity of productivity with respect to road density. In what follows, we discuss our estimates.

4.1 Industry-level Effects

To conduct our analysis, we construct a weakly balanced panel of industry-level log TFP in different states from 1998 until 2012 by averaging firm-level TFP ending up with 6714 observations. In estimating our model, we use the multipliers supplied by ASI and weight the regressions by an industry's employment in the initial study period. Hence, our results are representative of the entire population of organized manufacturing firms in India.

We begin by estimating a semi-log panel fixed effects model where we regress log TFP on road density and control for state-industry and year fixed effects. Thus, we estimate an equation of the form:

$$TFP_{jst} = \gamma(ROAD_{st}) + \theta_{js} + \phi_t + \mu_{jst} \qquad (6)$$

where TFP_{jst} is the average industry-level log TFP for industry j in state s at time t that correspond to α_{jst} in eq.(4). $ROAD_{st}$ is the road density for a state in a given year and γ is its marginal effect – the main coefficient of interest. θ_{js} denotes state-industry fixed effects; ϕ_t denotes year effects and μ_{jst} is an error term clustered at the state-industry level. We cluster our errors at the state-industry level because we want to account for possible correlations within a state-industry pair over time arising from ASI's sampling design or due to industry-specific policies that might vary across states.

Table 2 presents results from estimating the marginal effect of road density, γ. The panel fixed effects results (Table 2 columns 1 and 4) indicate that road density has no significant impact on TFP in our sample. However, as already discussed, the fixed effects estimates are likely to be biased due to the non-randomness of road placement. In fact, the coefficients are likely to be downward biased since the major thrust of the government has been to extend connectivity to remote habitations where existing productivity remains quite low in comparison to well-connected regions.

Columns 2 and 3 in Table 2 present the results of our IV estimation. Here, we instrument road density with the exogenous variation in the political alignment of a state's ruling party with the centre across multiple election cycles. Further, we include additional

13

Table 2: Effect of Road Density on TFP: Main Results

Variables	Valued added			Gross Output

F		41.99	35.36		41.99	35.36

Notes: In cols.(1)-(3) the dependent variable is log value-added TFP while in cols.(4)-(6) it is log gross-output TFP, both estimated using ACF method. FE shows results from a panel fixed effects model; IV-I from a panel 2SLS model that controls for state-industry and year fixed effects whereas, IV-II shows results from a panel 2SLS model that additionally controls for time-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – and a state's railway density. Road density is the total state-wide road length (in km) divided by its land area (in sq. km). RMSE=Root Mean Squared Error; F-stats>10 ∼ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

controls to maintain our exclusion restriction and to avoid omitted variables bias. We estimate our model with additional controls as:

$$TFP_{jst} = \gamma(Road_{st}) + \delta_t X_t + \zeta(Rail_{st}) + \theta_{js} + \phi_t + \varepsilon_{jst} \tag{7}$$

where X_{st}, is a vector of year interacted state-specific characteristics in logs with δ_t its corresponding coefficient vector that allow for different time trends according to these characteristics. We also control for a state's railway density, $Rail_{st}$ with coefficient ζ to purge the effect of railways on TFP and include state-industry and year fixed effects like in eq.(6). ε_{jst} denotes an idiosyncratic shock term. Columns 2 and 5 in Table 2 are results from a panel Two Stage Least Squares (2SLS) model where we regress TFP(VA) and TFP(GO) respectively, on road density instrumented by *Aligned*, conditional on state-industry and year fixed effects. Before we go any further, we need to consider whether our instrument is appropriate. Table 3 presents the first stage of our IV estimation where we regress road density on $Aligned_{st}$, conditioning on the full vector of controls to maintain our exclusion restriction. Our results show a significant positive advantage of political alignment: road density is 0.12-0.17 points higher when a state is aligned with the centre than when it is not aligned. These results are statistically significant at the 1% level of significance demonstrating that our instrument is suitable for the task at hand.

Returning to the IV estimates in Table 2, we find that our estimates for both the VA and GO measures are very similar and in what follows we will concentrate on the VA estimates. Column 3 provides estimates with the full range of controls where we find

Table 3: First Stage: Effect of Alignment on
Road Density

	(0.03)	(0.02)
Rail density	No	Yes
Year FE	Yes	Yes
Year x State variables	No	Yes
State-Industry FE	Yes	Yes
Observations	6651	6651
RMSE	0.357	0.324

Notes: Table shows first stage estimates from regress-
ing Road density on *Aligned* conditional on controls.
Standard errors clustered at state-industry level. *
$p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

that road density has a highly significant impact on TFP. Our results indicate that an additional km of road per sq.km area leads to about a 0.10 log point increase in TFP. We cluster the standard errors at the state-industry level for reasons already mentioned.

One concern is whether political alignment indeed affects road density or if it is merely an artefact of the data. To dispel this concern we conduct a placebo test motivated by Chetty et al. (2009) and Martin et al. (2017), where we randomly assign alignment status to a state during a year and use the constructed variable as our placebo instrument for road density. *Ex-ante* we would expect placebos to yield insignificant estimates. We conduct 100 placebo runs in total where each draw is from a Bernoulli distribution that preserves a state's historical alignment probability between 1998 and 2012. Table 4 presents results from one such draw where we find that the placebo instrument is not informative i.e. it has no significant effect on road density and neither does it affect TFP even after conditioning on the full set of controls.

Table 5 summarises the results from running the placebo test 100 times for TFP(VA) and TFP(GO), respectively. We get an insignificant result about 93 times for TFP(VA) and 92 times for TFP(GO) respectively, that largely reject the placebo instruments – the randomly assigned alignment status – in favour of true alignment status. Only 5 times out of 100 runs do we get a significant positive coefficient for the effect of road density on TFP(VA) at the 5% level of significance (6 times for TFP(GO)) whereas, the coefficient has incorrect sign and is negative in the remaining 2 cases for both TFP(VA) and TFP(GO).

In Figure 3, we plot the empirical cumulative distribution function (CDF) for the 100 placebo tests for TFP(VA) and TFP(GO). The true coefficients as shown by the vertical lines are towards the far right of the CDF in each case implying that our placebo test was successful.

Table 4: Placebo Instrument Test

	TFP(VA) (1)	TFP(GO) (2)	First Stage (3)

F	0.456	0.456	

Notes: Results from a single placebo test where we instrument a state's road density with a randomly assigned alignment status based on a Bernoulli distribution that preserves a state's alignment probability between 1998-2012. Placebos were assigned 100 times. This table shows one example of a placebo run. We include the full set of controls. See Table 2 for the full list of conditioning variables. RMSE=Root Mean Squared Error; F-stats>10 ∼ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 5: Summary Statistics of Placebo Tests

Variable	Above 0 (1)	Below 0 (2)	Insignificant (3)
TFP(VA)	5	2	93
TFP(GO)	6	2	92

Notes: In cols.(1) and (2), we show the number of runs when each outcome of interest was above or below 0 and significant at the 5% level, respectively, whereas in col.(3), we show the number of runs when the result did not turn out to be significant at the 5% level. Placebos were assigned 100 times.

(a) Empirical CDF, TFP(VA) (b) Empirical CDF, TFP(GO)

Figure 3: Figure shows empirical CDF distribution of 100 placebo runs and their true coefficients for value-added and gross output TFP (in logs), respectively. The vertical lines show the coefficients on true alignment status.

In the next section, we discuss the extent to which the effect of roads on TFP differ by age, size and location of firms within an industry.

4.2 Impact Heterogeneity

Our results so far clearly indicate that higher road density translates into positive TFP gains in manufacturing. What is not clear, however, is whether roads might have a differential effect on firms of different ages, sizes and location which might be particularly relevant to policy makers. In this section, we consider this issue in more detail by disaggregating our sample along these axes.

4.2.1 Young vs Incumbent Firms

We begin by examining whether roads differentially affect young firms relative to incumbents. We classify young firms as those within the first four years of establishment while we consider firms above this threshold as incumbents. We then aggregate firm-level TFP to the industry-level for these two different segments. The number of observations is smaller than the full sample as some industries do not have firms in a given year in the young category or in the incumbent category, as the case maybe.

Table 6 presents results for young and incumbent firms in the industry in Panels A and B respectively. We focus on columns 3 and 6 in Table 6 that consider the full-specification for TFP(VA) and TFP(GO), respectively. Our results indicate that a marginal increase in road density has a significant positive impact on the TFP of both young and incumbent firms. However, the magnitude of impact is larger for incumbents. A marginal increase in road density results in a 0.10 log point increase in TFP for incumbents (Panel B, Table 6) compared to a 0.08 log point increase for younger entrants (Panel A, Table 6). This is hardly surprising because younger entrants have already factored in location decisions at the entry-stage. Thus, the additional productivity gains from an improvement in road density for younger firms, once they have established, are smaller, than it is for incumbents who can now restructure their operation in response to higher road density that gets reflected in their productivity.

4.2.2 Small vs Large Firms

To consider whether the impact of roads on small firms is different in comparison to large ones, we classify firms as small if the real value of their fixed assets (land, buildings, machinery etc.) is lower than the industry's median value and we consider them as large if their fixed assets exceed the median value. We then aggregate the log normalised TFP values by firm size at the industry level resulting in about 6300 observations that relate to small firms and 6100 observations for large firms.

Table 6: Effect of Roads on TFP: Young vs. Incumbent

Variables	Valued added			Gross Output		
	FE (1)	IV-I (2)	IV-II (3)	FE (4)	IV-I (5)	IV-II (6)

Road density	0.003	0.066***	0.104***	0.003	0.067***	0.107***
	(0.00)	(0.02)	(0.03)	(0.00)	(0.02)	(0.03)
Observations	6595	6532	6532	6595	6532	6532
RMSE	0.045	0.052	0.056	0.044	0.051	0.056
F		39.67	32.40		39.67	32.40
Rail density	No	No	Yes	No	No	Yes
Year	Yes	Yes	Yes	Yes	Yes	Yes
Year x State variables	No	No	Yes	No	No	Yes
State-Industry FE	Yes	Yes	Yes	Yes	Yes	Yes

Notes: In cols.(1)-(3) the dependent variable is log value-added TFP while in cols.(4)-(6) it is log gross-output TFP both estimated using ACF method. FE shows results from a panel fixed effects model; IV-I from a panel 2SLS model that controls for state-industry and year fixed effects whereas, IV-II shows results from a panel 2SLS model that additionally controls for time-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – and a state's railway density. Panel A shows results that correspond to young firms aged$\leq$ 4 years in the industry whereas, Panel B shows results for incumbent firms in the industry aged $>$ 4 years. Road density is the total state-wide road length (in km) divided by its land area (in sq. km). RMSE=Root Mean Squared Error; F-stats$>$10 $\sim$ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 7 presents industry-level results for small and large firms in Panels A and B respectively. We find that, at the margin, roads benefit small firms more than they do large ones. Increasing road density raises TFP(VA) by about 0.12 log points (Columns 3 and 6, Panel A) for small firms whereas, it is about 0.08 (see Panel B, Table 7) for large firms. This difference in impact might be due to smaller firms being more flexible in restructuring their operation in response to increased road density. By contrast, larger firms might face rigidities in overhauling their production and supply structures that affect their ability to restructure operations in response to changing road density.

4.2.3 Rural vs Urban States

In this section, we examine if a denser road network affects firms in rural states differently than firms in urban states. We define a state as rural if its urban population is lower than the median value of urban population for all states in our sample.

In Table 8, we examine how the effect of roads on TFP(VA) differs by size and incumbency status of firms in rural and urban states, respectively in Panels A and B (see Table 14

Table 7: Effect of Roads on TFP: Small vs. Large

State-Industry FE	Yes	Yes	Yes	Yes	Yes	Yes

Notes: In cols.(1)-(3) the dependent variable is log value-added TFP while in cols.(4)-(6) it is log gross-output TFP both estimated using ACF method. FE shows results from a panel fixed effects model; IV-I from a panel 2SLS model that controls for state-industry and year fixed effects whereas, IV-II shows results from a panel 2SLS model that additionally controls for time-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – and a state's railway density. Panel A shows results that correspond to small firms in the industry with fixed assets lower than the industry median value of fixed assets whereas, Panel B shows results for large firms in the industry with fixed assets that exceed the industry median value of fixed assets. Road density is the total state-wide road length (in km) divided by its land area (in sq. km). RMSE=Root Mean Squared Error; F-stats>10 $\sim$ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

in Appendix B for the impact of roads on TFP(GO)). We condition our estimates on the full set of controls in each column. We find that the coefficient of road density is larger in Panel B indicating that an increase in road density benefits industries located in urban states more than those located in rural states. This might be due to the presence of complementarities in production in urban states that allow industries to capitalise the full benefits arising from higher road density. While the increase in TFP for industries located in rural states is about 0.13 log points (Panel A, column 1), it is about 0.22 log points for industries located in urban states (Panel B, column 1).

Considering the impact of roads on TFP by a combination of size, age and location, we find that the largest impact of roads is on younger entrants in urban states where TFP(VA) rises by more than 0.34 log points (Panel B, column 4) followed by small-sized firms in urban states where the coefficient of road density is 0.33 (Panel B, column 2). Thus, we find that the effect of roads on manufacturing TFP is considerably heterogeneous and varies across age, size and location of firms.

In the next section, we turn to results from long-differenced regressions.

Table 8: Effect of Roads on TFP (Value added): Rural vs. Urban

Variables	All (1)	Small (2)	Large (3)	Young (4)	Incumbent (5)

Rail density	Yes	Yes	Yes	Yes	Yes
Year	Yes	Yes	Yes	Yes	Yes
Year x State variables	Yes	Yes	Yes	Yes	Yes
State-Industry FE	Yes	Yes	Yes	Yes	Yes

Notes: The columns indicate log value-added TFP values for all firms in the industry (in col.(1)), for small firms (in col.(2)), for large firms (in col.(3)), for young firms (in col.(4)) and for incumbent firms in the industry (in col.(5)). Further, Panel A shows results for industries located in rural states where we classify a state to be rural if its urban population is less than the median urban population of all states in our sample while Panel B shows results for industries located in urban states i.e. states which exceed the median urban population. Road density is the total state-wide road length (in km) divided by its land area (in sq. km). The coefficients on road density are from separate regressions of the respective dependent variables on road density, controlling for year-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – a state's railway density and state-industry and year fixed effects. RMSE=Root Mean Squared Error; F-stats>10 $\sim$ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

4.3 Long-Differenced Results

Thus far, we consider the impact of roads on manufacturing productivity using state-industry panel data spanning from 1998 until 2012. However, building roads takes time and road infrastructure might need to reach a tipping point before it begins to affect productivity. On the other hand, it is possible that the impact of roads is transient, spurring a short burst in productivity as roads are built/ upgraded, but decays over time as firms readjust their operations. To investigate this, we consider the long horizon impact of road density on industry-level TFP by long-differencing our dependent variable, TFP(VA) and TFP(GO), as well as our main covariate, road density, over a span of 14 years. We do this by simply subtracting the values of these variables in 1998 from their corresponding values in 2012. Differencing in this way takes out time invariant factors at the state-industry level. Because our dependent variables are in logs, we can interpret the long-differenced dependent variable as the growth rate in productivity. We then regress the long-differenced variables on the change in road density between 1998 and 2012, which

Table 9: Effect of Roads on TFP: Long-Differenced Results

	ACF Method		LP Method		
	ΔTFP (VA) (1)	ΔTFP (GO) (2)	ΔTFP (VA) (3)	ΔTFP (GO) (4)	First Stage (5)
Δ Road density	0.078*** (0.02)	0.078*** (0.02)	0.077*** (0.02)	0.079*** (0.02)	
CAY$_{98\text{-}12}$ x Aligned$_{12}$					0.087*** (0.01)
Industry FE	Yes	Yes	Yes	Yes	Yes
State variables	Yes	Yes	Yes	Yes	Yes
Observations	298	298	298	298	298
RMSE	0.086	0.084	0.084	0.085	0.525
F			62.5		

Notes: Cols.(1) and (2) relate to long-differenced log value-added and gross-output TFP values between 1998 and 2012 respectively, estimated using Ackerberg, Caves and Frazer (2015) method. Cols.(3) and (4) relate to long-differenced log value-added and gross-output TFP respectively, estimated using the Levinsohn and Petrin (2003) method for the same time period. Col.(5) shows first stage results. ΔRoad density is the change in road density between 1998 and 2012 where road density is defined as total state-wide road length (in km) divided by its land area (in sq. km). We instrument road density with the continuous number of aligned year between 1998-2018 (CAY$_{98\text{-}12}$) conditional on being aligned in 2012 (Aligned$_{12}$). All regressions control for industry fixed effects and state characteristics – population, literacy, total main and marginal workers and total main workers in agriculture and industry. RMSE=Root Mean Squared Error; F-stats>10 $\sim$ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

we can write as:

$$\Delta TFP_{js} = \beta(\Delta ROAD_s) + \delta X_s + \theta_j + u_{js} \tag{8}$$

where the prefix Δ denotes that the variable is long-differenced and X_s denotes a vector of state-specific variables. Thus, in eq.(8), we examine the impact of a marginal increase in the change in road density between 1998 and 2012, $\Delta ROAD_s$, on the growth rate of productivity, ΔTFP_{js} . We instrument $\Delta ROAD_s$ in these estimations by the consecutive number of years for which a state was aligned with the centre between 1998 and 2012 conditional on it remaining aligned in 2012 and the set of controls X_s.

Table 9 shows results from these estimations. Columns 1 and 2 show results where the dependent variables are respectively TFP(VA) and TFP(GO), estimated using the ACF method. After controlling for endogeneity, we find that a marginal increase in the change in road density leads to about a 0.08 increase in the change in log TFP. Thus, we can conclude that, at the industry level, roads not only affect the scale of productivity (see Table 2), but also its growth (see Table 9).[9]

4.4 Elasticity of TFP

The above results show how road density affects manufacturing productivity either on an annual basis using panel data or in the longer term using long-differenced regressions.

---

[9]Columns 3 and 4 in Table 9 show that the long-differneced effects of roads on TFP estimated using the LP method are similar to that obtained by employing the ACF method in columns 1 and 2.

Table 10: Elasticity of TFP (Value Added) with respect to Road density

Variables	All (1)	Rural (2)	Urban (3)	Young (4)	Incumbent (5)	Small (6)	Large (7)
log(Road density)	0.120***	0.118***	0.442***	0.102*	0.120***	0.151***	0.091***
	(0.03)	(0.04)	(0.16)	(0.05)	(0.03)	(0.04)	(0.02)

Notes: Dependent variable is log TFP(VA) for the sub-sample indicated in columns (1-7). The results are from a panel 2SLS model that regresses TFP(VA) on log(Road density) where the latter is instrumented by *Aligned*. All regressions control for time-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – a state's railway density and include year and state-industry fixed effects. RMSE=Root Mean Squared Error; F-stats>10 $\sim$ valid instruments. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Another useful and perhaps more intuitive way to understand our results is to look at elasticity – the percentage change in TFP due to a one percent increase in road density. To obtain elasticity esimates we regress log TFP on log (Road density) where we instrument the latter with *Aligned* and include the full list of controls. Table 10 illustrates the elasticity of TFP with respect to road density as well as the extent to which the estimates show heterogeneous impact along firm size, age and location. We find that overall, a one percent increase in road density leads to a 12 percentage point increase in TFP. Mirroring earlier results from our semi-log model, the elasticity estimates show that the productivity of small firms, incumbents and those in urban states are more elastic to road density in relation to their respective counterparts. The productivity of large firms are the least elastic to road density (9.1%) whereas, firms in urban states are the most elastic (44%).

In the next section, we present results from robustness checks.

5 Robustness Checks

We conduct several robustness checks to validate our results. We briefly discuss them below.

- *Alternative measure of road density:* Here, we consider road density as a binary variable that takes a value of 1 if road density for a state-year exceeds the 60th percentile of the all states in our sample, and zero otherwise. Relaxing the functional form specification in this way allows us to capture discontinuities in the effect. The results are presented in Table 11 where we consider the effect of high road density on TFP(VA) and TFP(GO) in columns 3 and 6 respectively, and where high road

Table 11: Effect of High Road Density on TFP (VA and GO): FE and IV

Variables	Valued added			Gross Output		
	FE (1)	IV-I (2)	IV-II (3)	FE (4)	IV-I (5)	IV-II (6)
High Road density	0.003	0.442*	0.360**	0.003	0.449*	0.370**
	(0.00)	(0.23)	(0.16)	(0.00)	(0.23)	(0.16)
Rail density	No	No	Yes	No	No	Yes
Year FE	Yes	Yes	Yes	Yes	Yes	Yes
Year x State variables	No	No	Yes	No	No	Yes
State-Industry FE	Yes	Yes	Yes	Yes	Yes	Yes
Observations	6714	6651	6651	6714	6651	6651
RMSE	0.043	0.120	0.100	0.042	0.122	0.102
F		5.76	8.73		5.76	8.73

Notes: In cols.(1)-(3) the dependent variable is log value-added TFP while in cols.(4)-(6) it is log gross-output TFP both estimated using ACF method. FE shows results from a panel fixed effects model; IV-I from a panel 2SLS model that controls for state-industry and year fixed effects whereas, IV-II shows results from a panel 2SLS model that additionally controls for time-interacted state characteristics (in logs) – population, literacy, total main and marginal workers, total main workers in agriculture and industry – and a state's railway density. High Road density is a dummy variable that takes a value of 1 if log(Road density) in a state si greater than the 60 percentile of road density in all states in that year and 0 otherwise. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

density is instrumented by *Aligned*. The first stage results show that our instrument is appropriate (see Table 15 in the Appendix B). After controlling for endogeneity and including the full set of controls, we find that high road density raises log TFP by about 0.36-0.37 points relative to the base group – states with low road density. In comparison to previous results that use a continuous measure of road density, we observe that the magnitude of impact when using a binary measure is relatively large. The discontinuous jump in productivity from being in high road density states might be due to agglomeration effects as firms form spatial clusters or other complementarities in production that kick-in in high road density states.

- *Alternative Measures of TFP:* Throughout this article, we mainly focus on TFP estimated by the ACF method since it avoids the functional dependence problem that affects labour coefficients in Olley and Pakes (1996) type methods, as mentioned before. In Table 12, however, we present estimates using alternative measures of TFP. In column 1, we present results from regressions where we estimate TFP(VA) using the Levinsohn and Petrin (2003) method (see Table 16 in Appendix B for first stage results). We find that the effect of roads on TFP is robust to the choice of alternative measures and the results are quite similar to the ones obtained by the ACF method.[10]

---

[10]We note that our results hold even if we use the Wooldridge (2009) method but do not show the results to conserve space.

Table 12: Effect of Roads on TFP: Robustness Checks

Variables	LP(VA) (1)	Winsorised (2)	No Split States (3)	IV-A (4)	IV-B (5)
			Panel A: Value Added		
Road density	0.100***	0.100***	0.070***	0.063***	0.103***
	(0.03)	(0.03)	(0.02)	(0.02)	(0.03)
RMSE	0.053	0.054	0.046	0.048	0.055
			Panel B: Gross Output		
Road density	0.103***	0.101***	0.071***	0.064***	0.106***
	(0.03)	(0.03)	(0.02)	(0.02)	(0.03)
RMSE	0.054	0.053	0.046	0.047	0.054
Rail density	Yes	Yes	Yes	Yes	Yes
Year	Yes	Yes	Yes	Yes	Yes
Year x State variables	Yes	Yes	Yes	Yes	Yes
State-Industry FE	Yes	Yes	Yes	Yes	Yes
Observations	6651	6654	6463	6651	6651
F	35.36	35.36	34.89	72.60	36.38

Notes: The dependent variable in col.(1) is log value-added TFP estimated using LP method (Levinsohn and Petrin 2003). In col.(2), we winsorise the top 1% and bottom 1% of log value-added TFP estimated using ACF method. In col.(3), we exclude the states of Bihar, Jharkhand, Madhya Pradesh, Chhattisgarh, Uttar Pradesh and Uttarakhand that were re-organized in 2000 from our analysis. In cols.(4) and (5), we present results from regressions where we instrument road density with 'Aligned x Seat share' and 'Aligned x Election year dummy' as our instrument, respectively. Panel A relates to value-added TFP whereas, panel B relates to gross-output TFP, respectively. Road density is the total state-wide road length (in km) divided by its land area (in sq. km). All regressions include the full set of controls – time-interacted state-specific variables, a state's railway density along with year and state-industry fixed effects. Standard errors clustered at state-industry level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

- *Treating Outliers:* One important issue in working with establishment-level data is that outliers might unduly influence our estimates. To avoid this, we winsorise the top 1% and the bottom 1% of the distribution of log TFP and re-run our estimates. Column 2 in Table 12 presents results after 1%/99% winsorisation of the dependent variable. We find that, even after treating outliers in this way, our results remain almost identical, evidence that our results are robust to outliers.

- *Excluding Split States:* In 2000, three new states – Jharkhand, Chhattisgarh and Uttarakhand – were carved out of Bihar, Madhya Pradesh and Uttar Pradesh, respectively. It is possible that changes to state boundaries that reorganized the institutional mechanisms governing states affected state policies and hence industrial productivity in split states. One example of this is Uttarakhand which implemented tax incentive schemes to attract industries that affected productivity (see Chaurey 2016). To ensure that our results are robust to these changes, we exclude these six states and re-estimate our results. We find that excluding these states lowers the effect of roads on productivity to 0.07, as expected, but remains statistically significant at the 1% level (Column 3 in Table 12).

- *Alternative Instruments:* Thus far, we instrument road density with *Aligned*, a binary indicator for whether a state's ruling party is aligned with the centre during a year. However, since *Aligned* is a binary variable, we do not get a sense of whether the share of seats of the ruling party in a state has a bearing on the provision of roads, conditional on alignment. To examine this, we interact *Aligned* with the seat share of the ruling party and use this as our instrument (see column 4 in Table 12). This effectively distinguishes aligned parties in different states by weighing them in proportion to the share of seats they won in legislative assembly elections. Besides this, it is also important to examine if political factors are indeed driving our results. One way to examine this is to consider alignment during an election year. To do this we interact *Aligned* with a dummy for an election year (see column 5 in Table 12) and use it as an instrument for road density. We observe that: first, both the alternative instruments are informative (see Table 16 in Appendix B); and, second, the results in columns 4 and 5 in Table 12 are qualitatively similar to the estimates in column 3 in Table 2, adding to the credibility of our main estimates. In fact, as expected, the coefficient on road density with 'Aligned x Election year dummy' as instrument (IV-A) is marginally higher than when we used *Aligned* as instrument whereas, accounting for seat share of the aligned ruling-parties across states (IV-A) slightly lowers the estimate of roads.

6   Conclusion

In this article, we examine the role of road transport infrastructure on manufacturing productivity. By reducing transport costs and improving firm logistics, improved transportation infrastructure encourages specialisation, reduces inventory costs, extends the size of markets and increases trade. Here, we examine how road density affects multifactor productivity in the context of Indian manufacturing during 1998-2012.

An important challenge in estimating the effect of roads on manufacturing TFP is that the placement of roads is not random. For example, roads might be more prevalent in states that trade more i.e. when roads are built to support trade, or if they trade less i.e. where roads are built to encourage trade. Moreover, states producing more output are also likely to have greater capacity to invest in roads. We overcome this inference problem by exploiting exogenous variation in the timing and duration of partisan alignment of states with the centre across multiple election cycles that are staggered across states. The premise is that in a federal democracy, the centre is likely to favour states that are aligned with it over those that are not. This will influence the transfer of resources to states, allowing aligned states to deliver more public goods such as roads. Thus, *ex-ante* we expect road density within states to be higher when state governments are aligned with the centre than when states are not so aligned. Our first stage regression estimates

confirm that the average road density in India is higher during times when a state is aligned than when it is not aligned. Therefore, our study provides a political-economic explanation for differences in manufacturing productivity across states that arise out of differences in access to transport infrastructure.

To avoid omitted variable bias, we include state-industry fixed effects to control for unobserved time-invariant heterogeneities such as industry-specific policies within a state. We control for railway density and include year interacted state-specific variables such as population, literacy, total main and marginal workers etc. To absorb year specific volatility in cost or orders we control for year fixed effects.

After controlling for endogeneity and including the full set of controls, we find that at the industry-level an additional km of road per sq.km of area leads to a 010-0.34 log point rise in TFP. We find that this impact varies by age, size and location of firms within the industry. In particular, productivity gains are higher for small firms and for incumbents. The largest gains are in urban states. Analysing changes over the entire period (1998-2012), we find that the results confirm our findings from our panel data analysis. Moreover, our results are consistent across both the value-added and the gross-output TFP measures and across different methods to estimate productivity. To gain an intuitive understanding of our results we conduct elasticity estimates where we find that, on average, a one percentage point increase in road density leads to a 12 percentage point increase in industry-level TFP and that the heterogeneity in elasticity estimates mirror findings from the semi-log model.

We conduct several robustness checks to validate our results, including using alternative measures of both road density and productivity as well as an alternative instrument for road density. We winsorise our main dependent variable to guard against outliers and conduct a placebo test where we replace our true instrument, *Aligned*, with a random draw of alignment status. We find that our results are robust to all such checks.

Our results lead us to conclude that road transportation boosts manufacturing TFP. However, its impact differs by age, size and location of firms. Moreover, transport infrastructure itself is driven by political economic forces. These findings are particularly relevant for developing countries investing billions of dollars in building or upgrading its transportation network and in understanding how that affects trade and economic growth.

Appendix

A Variables Used to Estimate TFP

In estimating TFP, we used the following variables: gross value of output (or value added output), total man-days worked, raw materials, power and fuel. The values of gross and value-added output were converted into real terms by deflating the nominal values by industry-specific wholesale price indices (WPI) whereas, expenses on raw materials and power and fuels were deflated by overall WPI. The price indices were obtained from the Office of the Economic Adviser, GoI (see http://eaindustry.nic.in/home.asp).

We followed the methodology in Balakrishnan et al. (2000) to measure capital (see also Topalova and Khandelwal (2011) and Kathuria and Sen (2014) who follow this method). This method applies the perpetual inventory method while correcting for the fact that the book value of capital is measured at historic and not replacement cost. To arrive at a measure of capital stock at replacement costs for a base year, we first assume our base year to be 2006 since we have maximum observations for that year. We then compute a revaluation factor assuming that the life of a machine is twenty years, and that the price of capital and the growth of investment changes at a constant rate throughout the assumed twenty years lifetime of capital stock. We use the revaluation factor to convert base year capital to capital at replacement cost at current prices. We then deflate the current value by a deflator based on Gross Fixed Capital Formation (GFCF) series obtained from the Ministry of Statistics and Programme Implementation (MOSPI), GoI. Finally, we obtain our capital stock for every period by summing over investments in subsequent years.

Urban	3511	0.185	0.086	0.132	0.187	0.228	0.274
$\text{TFP}_{2012}/\text{TFP}_{1998}$	298	1.336	0.776	0.966	1.233	1.602	1.977

Notes: This table shows the dispersion of log gross-output Total Factor Productivity (TFP) in Indian manufacturing during 1998-2012 estimated using the Ackerberg, Caves and Frazer (2015) method. The firm-level log TFP values are normalised by dividing it by employment-weighted average productivity (in logs) for an industry-year. Row 'All' in the table corresponds to all observations in our sample. 'Young' includes industry-level estimates of only firms aged ≤ 4 years, whereas 'Incumbents' include those that are aged >4 years. 'Small' includes firms in the industry with fixed-assets lower than the median fixed assets in the industry, while 'Large' includes those with fixed assets greater than the industry median value. 'Rural' shows TFP for industries located in rural states where a rural state is defined to have urbanisation rate lower than the median value across all states in our sample.'Urban' shows TFP for industries located in states where the urbanisation rate exceeds the median value. $\text{TFP}_{2012}/\text{TFP}_{1998}$ is the ratio of log TFP values in 2012 and 1998.

Table 14: Effect of Roads on TFP (Gross output): Rural vs. Urban

Variables	All	Small	Large	Young	Incumbent
